Abstract

We report a case of severe gingival bleeding in a 15-year old, type 1 diabetic female. Examination revealed severe gingival inflammation with periodontal pockets (<6 mm), indicating mild-moderate periodontitis. Periodontal therapy resulted in reduction of fructosamine level (-72.98) after four weeks, but HbA1c level checked 3 months after treatment increased (+0.7). Reduction in gingival bleeding and periodontal pockets improved the patient’s quality of life. Insulin resistance is offered as a possible reason for non-improvement in HbA1c levels.

Key words: diabetes, periodontitis, glycated hemoglobin assay, diabetes camp, Diabetes Self-Management Education

INTRODUCTION

Glycated hemoglobin levels (HbA1c) reflect the blood sugar control over the preceding 1–3 months and has been found in studies to correlate well with the development of diabetic complications.¹ Periodontitis is an inflammatory disease initiated by an oral microbial film formerly known as plaque.² The host’s inflammatory response results in the destruction of the bone and soft tissue supporting the tooth.³ Periodontitis is now considered the 6th complication of diabetes due to the number of studies documenting its increased prevalence among diabetic patients.³ Periodontal treatment has shown a modest but significant reduction on HbA1c (-0.40%; 95% confidence interval) among diabetic patients but data in this meta-analysis were mostly from type 2 diabetic patients (T2DM).⁴ Treatment studies on type 1 diabetic (T1DM) patients have shown significant improvement in periodontal health, but this improvement is not reflected in the HbA1c levels like in T2DM patients.⁵⁻⁶

There are several differences between T1DM and T2DM. T1DM results from T-cell mediated pancreatic islet β-cell destruction which leads to absolute insulin deficiency.⁷ Serological markers of the autoimmune pathologic process or insulin auto antibodies are present in 85-90% of patients.⁸ T2DM on the other hand, occurs when insulin secretion is inadequate to meet the increased demand posed by insulin resistance.⁹ T2DM is commonly associated with inflammation, obesity and other features of insulin resistance.¹⁰ Although the development of these two types of diabetes is different, they both clinically manifest as an increase in blood sugar levels.

Clinically, patients with T2DM are frequently obese while those with T1DM are non-obese. The results of the Study of Health in Pomerania (SHIP) indicated that obesity was associated with both the extent and severity of periodontal disease along with markers of systemic inflammation in T2DM subjects.¹¹ C-reactive protein (CRP) is primarily a non-specific marker of inflammation and its levels rise in response to infections, autoimmune diseases and malignant processes.¹² Excessive periodontal disease and Body Mass Index are jointly associated with increased CRP levels in otherwise healthy, middle-aged adults.¹³

CASE

We report a 15-year-old female diagnosed with T1DM at age 8, during a diabetic ketoacidosis (DKA) episode. A second DKA episode occurred at age 11. She currently injects herself with premixed human insulin (70/30) twice a day, 40 units in the morning and 30 in the evening. She rarely monitors her blood sugar at home due to the high cost of glucose monitoring strips. The patient is 160 cm in height and weighs 53.7 kg. Her Body Mass Index (BMI=kg/m²) is 21.

Her last visit to the dentist was at 7 years old, before she was diagnosed with T1DM. Oral examination revealed severe bleeding of the gums with heavy calcular deposits (Figures 1a,1b). The patient also had halitosis (bad breath),

Improvement in Periodontitis in a Type 1 Diabetic Patient

Definitive Treatment

On follow-up after 20 months, a panoramic x-ray (Figure 5) did not show any significant bone destruction around the teeth. The following serological tests were requested: glycated hemoglobin assay (HbA1c), fructosamine test (a measure of glycemic control over the previous 2-3 weeks), and high sensitive C-Reactive Protein (hsCRP). HbA1c was determined using high performance liquid chromatography while fructosamine was determined using a colorimetric reaction with nitro blue tetrazolium. The hsCRP was determined by the agglutination method. The patient was also referred to a physician to confirm if any undiagnosed diabetic complications were present. Pocket probing depth (PPD) was measured and recorded (Table 2). PPD is the distance between the marginal gingival and the bottom of the gingival sulcus (Figures 3a, 3b) and is measured in 6 sites.

Figures 1a and 1b. Patient’s initial oral examination revealed severe bleeding of the gums and heavy calculus deposits.

Figures 2a and 2b. Gum bleeding was significantly reduced after only 4 sessions of scaling but the traces of inflammation can still be seen on the marginal gingival and interdental papilla.

Figure 5. Panoramic x-ray showing no caries and no obvious bone loss.
around the tooth, using a periodontal probe with calibrated marking to indicate depth in millimeters. Bleeding on probing (BOP) was given a score of: "1" when a dot of blood appears on the gingival margin following probing, "2" when a line of blood appears, and "3" when blood overflowed the gingival margin (Figure 3b) and is indicative of the degree of inflammation that is present. Tooth mobility is a measure of the amount of alveolar bone loss around the tooth; none was detected, consistent with the panoramic x-ray mentioned earlier. A PPD of \( \geq 4 \) mm is indicative of the presence of periodontitis. Oral hygiene instructions were reviewed together with diabetes self-management strategies.

### Figures 3a and 3b. Pocket probing prior to root planing procedure. Tendency of the gums to bleed is manifest and gingival architecture reveals pronounced swelling especially in the interdental papilla areas.

The patient was provided with the following prior to start of treatment: insulin and glucose strips for blood glucose home monitoring, toothbrushes, triclosan/copolymer toothpastes, dental floss, interdental toothbrushes, 0.12% chlorhexidine gluconate mouthwash (up to 6 weeks post-root planing) and a 0.075% cetyl pridinium chloride mouthwash (for use after 6 weeks post-root planing). Patient was asked to continue brushing her teeth three times a day and to floss at least once a day. She was also instructed to use the mouthwash twice a day. Root planing was performed for the maxillary teeth and the mandibular teeth on two separate occasions, within a span of 1 week.

The patient was asked to keep a record of her blood glucose levels, food intake, insulin dose and oral hygiene practices.

### Treatment Outcomes

Orally, diminution of inflammation and bleeding required 4 sessions of scaling (Figures 2a, 2b). Following root planing, there was an \(~60\%\) decrease (from 55 to 22) in sites with \(4-6\) mm PPD and there was an \(~30\%\) decrease (from 20 to 13) in the number of teeth with bleeding on probing score greater than 0 (Table 3, Figures 4a, 4b).
Severe Hypertriglyceridemia Presenting as Superior Sagittal Sinus Thrombosis

during the initial treatment and four sessions of scaling to ascertain its presence.

This case report is important because it provides a

inexpensive and clearly beneficial to the patient. The

greater than 4 mm and several teeth continued to exhibit

mg/dL over this time.

Subjectively, the patient reported that her quality of life

Figures 4a and 4b. Marked resolution of inflammation on the

interdental papilla areas. Gingival bleeding was markedly

reduced but gingival margin still appears swollen.

Serologically, there was a decrease (~20%) in fructosamine

levels (from ~362 umol/L to ~289 umol/L) 1 month

following periodontal therapy, which remained relatively

constant. HbA1c levels increased (from 9.1% to 9.8) three

months from the time of the initial visit while hsCRP

levels also slightly increased from 0.13 mg/dL to 0.15

mg/dL over this time.

Subjectively, the patient reported that her quality of life

greatly improved. She stated that she overcame her

shyness and fear of talking close to people, now laughs out

loud without covering her mouth and is considered one of

the “noisy girls” in her class.

DISCUSSION

This case report is important because it provides a

demonstration of how conservative periodontal therapy

can improve the quality of life an adolescent T1DM

patient. Treatment was conservative and relatively

inexpensive and clearly beneficial to the patient. The

limitation of this case report lies in the single subject and

that insulin resistance was not directly measured in order
to ascertain its presence.

Poor response to periodontal therapy was observed
during the initial treatment and four sessions of scaling
and polishing was required to reduce gingival bleeding.
This was again observed when response to root planing
did not result in the improvement of all pocket depths
greater than 4 mm and several teeth continued to exhibit
BOP greater than 0. Failure on the part of the patient to
follow oral hygiene instructions and/or the dentist’s

inability to clean the root surfaces well may account for

these results.

Another possible reason which we propose is the presence
of insulin resistance in the patient. The patient was
observed to have considerably more fat deposits
compared to a previous type 1 diabetic we treated
similarly. An analysis of the National Health and
Nutrition Examination Survey III data showed that

overweight individuals with IR in the highest quartile
exhibited more severe periodontitis compared to subjects
with high Body Mass Index and low IR.

Insulin resistance is thought to be associated only in T2DM
but not in T1DM because insulin resistance has been
documented in the development of T2DM but not on
T1DM. Furthermore few studies have studied insulin
resistance in T1DM patients because tools for measuring
insulin resistance in T2DM are not applicable to T1DM,
and those that are applicable are costly and invasive.
A hospital-based study on adult type 1 diabetics in the
Philippines, using estimated glucose disposal rate, showed
the prevalence of IR was 53% in the studied population.

The patient’s HbA1c increased from 9.1% from baseline to
9.8% after 3 months. It is difficult to reconcile the different

in the HbA1c test and the fructosamine test at first. However,
if you consider the proximity of the

insulin resistance test to the root planing procedure, the

reduction can certainly be attributed in part to periodontal
treatment. There may be several reasons for the lack of

improvement in the HbA1c: (1) the improvement in her
oral status might have caused an increase in food intake;
(2) the treatment period coincided with the holiday season.
(Christmas) where people eat more to celebrate; and (3) An adjustment in her insulin dose may have been warranted since baseline HbA1c was already elevated.

CONCLUSION

Conservative management of periodontitis using root planing is effective not only in reducing the oral health outcomes and appears to reduce blood sugar in the short term but not using longer term tests like HbA1c.
